Abstract

The transverse momentum Q_T distribution is computed for inclusive Higgs boson production at the energy of the CERN Large Hadron Collider. We focus on the dominant gluon-gluon subprocess in perturbative quantum chromodynamics and incorporate contributions from the quark-gluon and quark-antiquark channels. Using an impact-parameter b -space formalism, we include all-orders resummation of large logarithms associated with emission of soft gluons. Our resummed results merge smoothly at large Q_T with the fixed-order expectations in perturbative quantum chromodynamics, as they should, with no need for a matching procedure. They show a high degree of stability with respect to variation of parameters associated with the non-perturbative input at low Q_T . We provide distributions $d\sigma/dy dQ_T$ for Higgs boson masses from M_Z to 200 GeV. The average transverse momentum at zero rapidity y grows approximately linearly with mass of the Higgs boson over the range $M_Z < m_h < 200$ GeV, $\langle Q_T \rangle \simeq 0.18m_h + 18$ GeV. We provide analogous results for Z boson production, for which we compute $\langle Q_T \rangle \simeq 25$ GeV. The harder transverse momentum distribution for the Higgs boson arises because there is more soft gluon radiation in Higgs boson production than in Z production.

I. INTRODUCTION

The breaking of electroweak symmetry in the standard model (SM) of elementary particle interactions is achieved through the Higgs mechanism. In the simplest realization, a complex Higgs doublet is introduced, and a single neutral CP-even Higgs boson is predicted. Two Higgs doublets are expected at low energies in supersymmetric extensions of the standard model. The lightest neutral CP-even Higgs particle h resembles the SM Higgs boson in most regions of parameter space of broken supersymmetry [1]. Direct experimental searches at the CERN Large Electron Positron Collider (LEP) based on the presumption of significant decay branching ratio into bottom (b) quarks place the mass of a SM-like Higgs state above approximately 115 GeV [2]. An alternative analysis, based on the assumption of Higgs boson decay into hadronic jets, without b -tagging, provides a bound of about 113 GeV [3]. A good theoretical description of electroweak data [4] in the framework of the SM requires the Higgs boson to be lighter than about 200 GeV [2]. Within the minimal supersymmetric standard model (MSSM), the upper bound on the mass of the lightest Higgs state is roughly 135 GeV [5]. The search for the Higgs boson is a central motivation for the experimental programs at the Fermilab Tevatron and the CERN Large Hadron Collider (LHC), with detection techniques guided by theoretical expectations about its production dynamics and decay properties.

A Higgs boson resembling one anticipated by the SM is expected to be discovered at the LHC through various partonic production processes and decays to SM particles [6, 7]. These include

- $gg \rightarrow hX$, with $h \rightarrow \gamma\gamma$, $h \rightarrow W^+W^-$, or $h \rightarrow ZZ$;
- $gg \rightarrow t\bar{t}hX$, with $h \rightarrow b\bar{b}$ or $h \rightarrow \gamma\gamma$; and
- $W^+W^-(ZZ) \rightarrow hX$, with $h \rightarrow W^+W^-$, $h \rightarrow \gamma\gamma$, or $h \rightarrow \tau^+\tau^-$.

The fully inclusive gluon-gluon fusion subprocess [8, 9] $gg \rightarrow hX$ is the dominant mechanism of production. In this process, production occurs through triangle loops of colored (s)particles that couple to the Higgs boson and to gluons. In the SM, the most relevant contribution is from a loop of top (t) quarks, with a small contribution from bottom quark loops. In supersymmetric theories, the bottom quark loop contribution can be important for small m_A and large values of $\tan\beta$, where m_A is the mass of the pseudo-scalar Higgs

boson and $\tan\beta$ is the ratio of Higgs vacuum expectation values. In the MSSM, loops of bottom squarks may make an important contribution if the mass of the bottom squark is light enough [10].

Semi-inclusive production of the Higgs boson in association with top quarks, $gg \rightarrow t\bar{t}hX$, has a relatively low rate because of the large masses in the final state. The semi-inclusive weak boson fusion modes [11] $W^+W^-(ZZ) \rightarrow hX$ require identification of (forward) “trigger” jets from subprocesses such as $qq \rightarrow qqWW \rightarrow qqhX$. Searches at the Tevatron rely on associated production of the Higgs boson with weak bosons, W and Z , and the decay mode $h \rightarrow b\bar{b}$ [12].

For masses m_h of the Higgs boson up to about 150 GeV, the SM Higgs boson produced in the gluon fusion process should be discovered at the LHC in the rare di-photon decay mode $h \rightarrow \gamma\gamma$ [6, 7]. Once data are in hand, the immense $\gamma\gamma$ background from various sources can be determined from the data by a measurement of the di-photon invariant mass distribution $d\sigma/dM_{\gamma\gamma}$ on both sides of the Higgs resonance. Beforehand, precise theoretical calculations of the expected differential cross sections for production of the signal and backgrounds [13, 14, 15] are important for quantitative evaluation of the required measurement accuracies and detector performance. Good estimations of the expected transverse momentum distributions can suggest selections in this variable that should improve background rejection. In this paper, we concentrate on behavior of the Higgs boson transverse momentum distribution in the region of small and intermediate values of Q_T .

Above W^+W^- threshold but below Z -pair threshold, the decay mode $h \rightarrow W^+W^-$ has a branching ratio approaching 100%. Because there are missing neutrinos in the leptonic decay modes of the W ’s, the invariant mass distribution of the Higgs boson cannot be reconstructed directly, but the transverse mass spectrum of the $(\ell^+ \ell^- \cancel{E}_T)$ system can be measured. This distribution is expected to be broad, and straightforward sideband determinations of the background are not possible. However, measurements of the backgrounds in regions in which the signal is expected to be absent can then be extrapolated into the expected signal region provided that good predictions are available of differential cross sections.

In the SM, the coupling of gluons to the Higgs boson through the top quark loop is simplified in the limit of large top quark mass m_t . In this limit, the relevant Feynman diagrams are obtained from an effective Lagrangian [16]. For inclusive production integrated over all transverse momentum, the next-to-leading order contributions in perturbative quantum

chromodynamics (QCD) are reported in Ref. [17]. The $m_t \rightarrow \infty$ approximation is valid to an accuracy of $\sim 5\%$ for $m_h \leq 2m_t$. Within this approach, the total cross section for $gg \rightarrow hX$, is known to next-to-next-to-leading order accuracy [18].

Computations of the transverse momentum distribution for Higgs boson production at leading order in perturbative QCD [19] show that the large m_t approximation serves well when the Higgs boson mass m_h is less than twice the top quark mass and the Higgs boson transverse momentum Q_T is less than m_t . The next-to-leading order contributions to the transverse momentum distribution are computed with numerical integration methods in Ref. [20]. The doubly-differential cross section in rapidity and transverse momentum of the Higgs boson is computed analytically at next-to-leading order in Refs. [21] and [22].

When the transverse momentum Q_T is comparable to the mass m_h of the Higgs boson, there is only one hard momentum scale in the perturbative expansion of the cross section as a function of the strong coupling α_s , and fixed-order computations in perturbative QCD are expected to be applicable. However, in the region $Q_T \ll m_h$, where the cross section is greatest, the coefficients of the expansion in α_s depend functionally on logarithms of the ratio of the two quantities, m_h and Q_T . A well-studied case is the cross section for gauge boson (W, Z, or virtual photon) production in hadronic collisions, at measured transverse momentum. The logarithmic term is $(\alpha_s/\pi) \ln^2(Q^2/Q_T^2)$ where Q is the mass of the boson and Q_T its transverse momentum. For Higgs boson production at $m_h = 125$ GeV, the peak of the transverse momentum distribution is expected to occur near $Q_T = 14$ GeV at LHC energies, as is shown in this paper. Correspondingly, $\ln^2(m_h^2/Q_T^2) \sim 19$ and $(\alpha_s(\mu)/\pi) \ln^2(m_h^2/Q_T^2) \sim 0.7$ if $\mu = m_h$ or ~ 1.1 if $\mu = Q_T$. In either case, the relevant expansion parameter in the perturbative series is close to 1, meaning that higher order contributions in perturbation theory are not suppressed. When $Q_T \ll m_h$, straightforward perturbation theory is inapplicable. Indeed, even at leading order in α_s , the computed cross section $d\sigma/dQ_T^2$ includes a term proportional to $(\alpha_s/Q_T^2) \ln(m_h^2/Q_T^2)$. This divergence as $Q_T \rightarrow 0$ is obviously unphysical.

All-orders resummation is the established method for mastering the large logarithmic coefficients of the expansion in α_s and for obtaining well-behaved cross sections at intermediate and small Q_T [23, 24, 25]. It is a reorganization of the perturbative expansion that brings the large logarithmic terms under systematic control, providing finite predictions for the Q_T dependence that are different from those at fixed order. Resummation overcomes the limitations of fixed-order calculations but still incorporates all the information that these

calculations offer.

Resummation may be carried out in either Q_T [25] or impact parameter (b) space, which is the Fourier conjugate of Q_T space. All else being equal, the b space approach has the advantage that transverse momentum conservation is explicit. Using renormalization group techniques, Collins, Soper, and Sterman (CSS) [24] devised a b space resummation formalism that resums all logarithmic terms as singular as $(1/Q_T^2) \ln^n(Q^2/Q_T^2)$ when $Q_T \rightarrow 0$. This formalism has been used widely for computations of the transverse momentum distributions of vector bosons in hadron reactions [26, 27, 28, 29, 30, 31, 32, 33, 34], Higgs bosons [35, 36, 37, 38, 39], and other processes [14, 40].

In many of these applications of the CSS formalism, two difficulties significantly limit its predictive power in the region of small and intermediate values of Q_T . The first of these is the ambiguity, if not discontinuity in Q_T , associated with the “matching” of the resummed and fixed-order calculations in a region of Q_T below which the resummed form is used, and above which a fixed-order expression is used. The second difficulty is associated with the quantitative importance of assumed forms for non-perturbative functions that, in many implementations, dominate the Q_T distribution in the region of very small Q_T and affect even the Q_T distribution at large Q_T . In recent papers [32], Qiu and Zhang demonstrate that both of these drawbacks can be overcome. By using an integral form for the oscillatory Bessel function in the Fourier transform, they show that the b -space resummation procedure produces smooth distributions for all $Q_T < Q$, obviating the need for a matching prescription. Second, to substantially reduce the influence of phenomenological non-perturbative functions, they derive a new functional expression that extrapolates the perturbatively calculated b -space resummation expression from the region of small b , where it is valid, to the region of large b where non-perturbative input is needed. Their analysis shows that perturbation theory itself indicates the form of the required non-perturbative power corrections. They also demonstrate that the predictive power of resummation improves considerably with total center-of-mass collision energy $\sqrt{S}$. In this paper, we further develop the methodology of Qiu and Zhang and use it to study the production of Higgs bosons.

In Sec. II, we review the pertinent aspects of the b -space resummation formalism, with particular emphasis on Higgs boson production. Working at next-to-leading-logarithm (NLL) accuracy, we resum both leading and next-to-leading logarithmic terms associated with soft gluon emission to all orders in α_s . At LHC energies, the typical values of the

incident parton momentum fractions $x_A \sim x_B \sim m_h/\sqrt{S} \sim 0.009$ (for $m_h = 125$ GeV) are small, and the gluon distribution evolves steeply at small x . Consequently, the saddle point in b of the Fourier transform from b -space to Q_T space is well into the region of perturbative validity. Resummed perturbation theory is valid at small b , just as perturbative QCD is valid at large Q_T . However, the Fourier transform from b -space to Q_T -space requires specification of the b -space distribution for all b . In Sec. III, we show that the region of large b becomes progressively less important quantitatively as $\sqrt{S}$ increases. The Q_T distribution at LHC energies is entirely insensitive to the functional form we employ for the non-perturbative input at large b , so long as the form used for this extrapolation does not modify the b -space distribution at small b . In Sec. III.B, we discuss the extrapolation from the region of small b to the region of large b , and we specify the form we use for the non-perturbative functions at large b . We discuss why other approaches in the literature may introduce inappropriate dependence on $\sqrt{S}$. We provide analytic expressions for the fixed-order perturbative subprocesses in Sec. IV. We employ expressions for the parton-level hard-scattering functions valid through first-order in α_s , including contributions from the glue-gluon, quark-gluon, and quark-antiquark incident partonic subprocesses.

Numerical predictions are presented in Sec. V. We show the doubly differential cross section $d\sigma/dy dQ_T$ as a function of Q_T at fixed rapidity $y = 0$, and the Q_T distributions for rapidity integrated over the interval $|y| < 2.4$. We present results for four choices of mass of the Higgs boson, values that span the range of present interest in the SM, from $m_h = M_Z = 91.187$ GeV to $m_h = 200$ GeV. To illustrate interesting differences, we also show our results for Z boson production at the same energy. Our resummed results make a smooth transition to the fixed-order perturbative results near or just above $Q_T = Q$, for all Q , without need of a supplementary matching procedure. Our implementation of the resummation formalism works smoothly throughout the Q_T region even for the distributions differential in rapidity, $d\sigma/dy dQ_T$. Two points are evident in the comparison of Z boson and Higgs boson production, with $m_h = M_Z$. The peak in the Q_T distribution occurs at a smaller value of Q_T for Z production (4.8 GeV *vs.* 10 GeV) and the distribution is narrower for Z production. The larger QCD color factors produce more gluonic showering in the glue-gluon scattering subprocess that dominates inclusive Higgs boson production than in the fermionic subprocesses relevant for Z production. After all-orders resummation, the enhanced showering suppresses the large- b (small Q_T) region more effectively for Higgs

boson production. We compare the predicted Q_T distributions for Higgs boson production at different masses. The peak of the distribution shifts to greater Q_T as m_h grows, in approximately linear fashion, and the distribution broadens somewhat. The mean value $\langle Q_T \rangle$ grows from about 35 GeV at $m_h = M_Z$ to about 54 GeV at $m_h = 200$ GeV, and the root-mean-square grows from about 59 GeV to about 87 GeV. For Z production, we find $\langle Q_T \rangle = 25$ GeV and $\langle Q_T^2 \rangle^{1/2} = 38$ GeV. The harder Q_T spectrum suggests that the signal to background ratio can be enhanced if Higgs bosons are selected with large Q_T .

Choices of variable parameters are made in obtaining our results, and we examine the sensitivity of the results to these choices, including the renormalization/factorization scale μ and the non-perturbative input. Scale dependence is the most important source of uncertainty. It can shift the position of the peak by about 1 GeV, with corresponding changes in the normalization of the distribution above and below the position of the peak. The value of $d\sigma/dy dQ_T$ at the peak position is shifted by 4 to 5%. Changes in the parameters of the non-perturbative input produce effects that at most 1 to 2% depending on the size of the power corrections we introduce. In the formulation we use to describe the non-perturbative region, there is essentially no effect on the behavior of differential cross section at large Q_T . In comparison with prior work, we note that the locations of the maxima in the distributions $d\sigma/dy dQ_T$ occur at slightly larger values of Q_T in our case, and the distributions themselves differ as a function of Q_T above the location of the maximum. The differences arise from the different treatment of the non-perturbative input. In our approach, the assumed parametrization of non-perturbative effects has the desirable property that it does not affect the physics in the perturbative region $b < 0.5$ GeV.

Conclusions are summarized in Sec. VI.

II. ALL-ORDERS RESUMMED Q_T DISTRIBUTION

We consider the inclusive hadronic reaction in which a color neutral heavy boson of invariant mass Q is produced:

$$A(P_A) + B(P_B) \rightarrow C(Q) + X, \quad (1)$$

with $C = \gamma^*, W^\pm, Z$, or a Higgs boson in the limit in which the top quark mass $m_t \gg Q/2$. The square of the total center-of-mass energy of the collision is S . At the LHC, $\sqrt{S} = 14$ TeV.

In the CSS resummation formalism, the differential cross section is written as the sum

$$\frac{d\sigma_{AB \rightarrow CX}}{dQ^2 dy dQ_T^2} = \frac{d\sigma_{AB \rightarrow CX}^{(\text{resum})}}{dQ^2 dy dQ_T^2} + \frac{d\sigma_{AB \rightarrow CX}^{(\text{Y})}}{dQ^2 dy dQ_T^2}. \quad (2)$$

The all-orders resummed term is a Fourier transform from b -space

$$\begin{aligned} \frac{d\sigma_{AB \rightarrow CX}^{(\text{resum})}}{dQ^2 dy dQ_T^2} &= \frac{1}{(2\pi)^2} \int d^2b e^{i\vec{Q}_T \cdot \vec{b}} W_{AB \rightarrow CX}(b, Q, x_A, x_B) \\ &= \int \frac{db}{2\pi} J_0(Q_T b) b W_{AB \rightarrow CX}(b, Q, x_A, x_B), \end{aligned} \quad (3)$$

where J_0 is a Bessel function. The function $W_{AB \rightarrow CX}(b, Q, x_A, x_B)$ resums to all orders in QCD perturbation theory the singular terms that would otherwise behave as $\delta^2(Q_T)$ and $(1/Q_T^2) \ln^m(Q^2/Q_T^2)$, for all $m \geq 0$. The variables x_A and x_B are light-cone momentum fractions carried by the incident partons from hadrons A and B :

$$x_A = \frac{Q}{\sqrt{S}} e^y \quad \text{and} \quad x_B = \frac{Q}{\sqrt{S}} e^{-y}, \quad (4)$$

and y is the rapidity of the heavy boson. The variables x_A and x_B do not depend on Q_T .

Resummation treats only the parts of the fixed-order QCD expression that are at least as singular as Q_T^{-2} in the limit $Q_T \rightarrow 0$. The remainder, including possible less singular pieces of the fixed-order perturbative contribution, is defined as the difference of the cross section computed at fixed order n in perturbation theory and its $Q_T \ll Q$ asymptote that is at least as singular as Q_T^{-2} .

$$\frac{d\sigma_{AB \rightarrow CX}^{(\text{Y})}}{dQ^2 dy dQ_T^2} = \frac{d\sigma_{AB \rightarrow CX}^{(\text{pert})}}{dQ^2 dy dQ_T^2} - \frac{d\sigma_{AB \rightarrow CX}^{(\text{asym})}}{dQ^2 dy dQ_T^2}. \quad (5)$$

This remainder is not significant quantitatively at modest Q_T , since the dominant singularities of the two terms on the right-hand-side cancel in the region $Q_T \rightarrow 0$. However, the difference becomes important when $Q_T \sim Q$. Explicit expressions for the fixed-order remainder terms are presented in Sec. IV.

We may factor out the lowest order partonic cross section and rewrite the function $W_{AB \rightarrow CX}(b, Q, x_A, x_B)$ that appears in the integrand of Eq. (3) as

$$W_{AB \rightarrow CX}(b, Q, x_A, x_B) = \sum_{ij} W_{ij}(b, Q, x_A, x_B) \sigma_{ij \rightarrow CX}^{(0)}(Q). \quad (6)$$

Here, $\sigma_{ij \rightarrow CX}^{(0)}(Q)$ is the lowest order cross section for a pair of partons of flavor i and j to produce a heavy boson of invariant mass Q . Because the heavy boson is color neutral, the parton flavors ij can be either the quark-antiquark or the gluon-gluon combination.

A. Higgs boson production

Specializing to Higgs boson h production in gluon-gluon fusion (and using m_h and Q interchangeably for the Higgs boson mass in the remainder of this paper), we write

$$W_{AB \rightarrow hX}(b, Q, x_A, x_B) = W_{gg}(b, Q, x_A, x_B) \sigma_{gg \rightarrow hX}^{(0)}(Q). \quad (7)$$

In the effective Lagrangian approximation [16, 17] where we keep only the contribution from the top quark loop, the lowest order partonic cross section for $gg \rightarrow hX$ is

$$\sigma_{gg \rightarrow hX}^{(0)}(Q) = \sigma_0 \frac{\pi}{S} m_h^2 \delta(Q^2 - m_h^2), \quad (8)$$

with

$$\sigma_0 = \left(\sqrt{2} G_F \right) \frac{\alpha_s^2(\mu_r)}{576\pi}. \quad (9)$$

In this expression, G_F is the Fermi constant, and μ_r denotes a renormalization scale. We note that σ_0 is formally of second order in the strong coupling strength. However, we *define* σ_0 be the effective 0'th order cross section and focus on the influence of yet higher order contributions. If we were to include contributions other than from top quarks in the loop, whether from bottom quarks or bottom squarks, we could easily replace σ_0 by a different expression. This inclusion would change the overall normalization of our predictions. For on-mass-shell gluons, QCD corrections to the ggh effective vertex are known to order α_s^2 [41] and likewise could be incorporated in a change in the numerical value of the effective σ_0 .

For comparison with Eq. (8), we also present the expression for the lowest order massive lepton-pair Drell-Yan cross section:

$$\sigma_{q\bar{q} \rightarrow \ell^+ \ell^- X}^{(0)}(Q) = e_q^2 \frac{4\pi^2 \alpha_{em}^2}{9SQ^2}. \quad (10)$$

B. Evolution equation for resummation

Resummation of the large logarithmic terms is achieved in the CSS formalism through a solution of the evolution equation

$$\frac{\partial}{\partial \ln Q^2} W_{gg}(b, Q, x_A, x_B) = \left[K_g(b\mu, \alpha_s(\mu)) + G_g\left(\frac{Q}{\mu}, \alpha_s(\mu)\right) \right] W_{gg}(b, Q, x_A, x_B), \quad (11)$$

where the subscripts g and gg indicate the gluonic process. There are two physical momentum variables in this expression, Q and $1/b$, as well dependence on the scale variable μ that, in principle, could take on values from of order $1/b$ to of order Q . However, the μ dependence of K_g and G_g is determined by renormalization group equations (RGE's),

$$\frac{\partial}{\partial \ln \mu^2} K_g(b\mu, \alpha_s(\mu)) = -\frac{1}{2} \gamma_g(\alpha_s(\mu)), \quad (12)$$

$$\frac{\partial}{\partial \ln \mu^2} G_g\left(\frac{Q}{\mu}, \alpha_s(\mu)\right) = \frac{1}{2} \gamma_g(\alpha_s(\mu)). \quad (13)$$

The RGE's for K_g and G_g ensure that $d/d \ln(\mu^2)[W_{gg}(b, Q, x_A, x_B)] = 0$ perturbatively, an expression that is consistent with the fact that W_{gg} is effectively a physical observable. The coefficients $\gamma_g^{(n)}$ in an expansion of the anomalous dimension $\gamma_g(\alpha_s(\mu)) = \sum_{n=1} \gamma_g^{(n)}(\alpha_s(\mu)/\pi)^n$ are calculable perturbatively.

The RGE's for K_g and G_g may be integrated over $\ln(\mu^2)$ from $\ln(C_1^2/b^2)$ to $\ln(\mu^2)$, and from $\ln(\mu^2)$ to $\ln(C_2^2 Q^2)$, respectively, where C_1 and C_2 are integration constants. The values of C_1 and C_2 are somewhat arbitrary. Following CSS, we select $C_1 = c = 2e^{-\gamma_E} = \mathcal{O}(1)$, where Euler's constant $\gamma_E \approx 0.577$, and $C_2 = 1$. After the integrations, one derives

$$K_g(b\mu, \alpha_s(\mu)) + G_g(Q/\mu, \alpha_s(\mu)) = - \int_{c^2/b^2}^{Q^2} \frac{d\bar{\mu}^2}{\bar{\mu}^2} A_g(\alpha_s(\bar{\mu})) - B_g(\alpha_s(Q)), \quad (14)$$

where A_g is a function of $\gamma_g(\alpha_s(\bar{\mu}))$ and $K_g(c, \alpha_s(\bar{\mu}))$ while B_g depends on both $K_g(c, \alpha_s(Q))$ and $G_g(1, \alpha_s(Q))$. The choice of $C_1 = c = 2e^{-\gamma_E}$ and $C_2 = 1$ has the virtue of removing logarithmic dependence on these parameters from the functions A_g and B_g .

The functions A_g and B_g are free of logarithmic dependence and have well-behaved perturbative expansions

$$A_g(\alpha_s(\bar{\mu})) = \sum_{n=1} A_g^{(n)} \left(\frac{\alpha_s(\bar{\mu})}{\pi} \right)^n \quad \text{and} \quad B_g(\alpha_s(\bar{\mu})) = \sum_{n=1} B_g^{(n)} \left(\frac{\alpha_s(\bar{\mu})}{\pi} \right)^n. \quad (15)$$

The first two coefficients in the expansions for A and B are known [37, 38, 39]. For the choices $C_1 = c = 2e^{-\gamma_E}$ and $C_2 = 1$, these are

$$\begin{aligned}
A_g^{(1)} &= C_A, \\
A_g^{(2)} &= \frac{C_A}{2} \left[C_A \left(\frac{67}{18} - \frac{\pi^2}{6} \right) - \frac{5}{9} n_F \right], \\
B_g^{(1)} &= -\frac{11C_A - 2n_F}{6}, \\
B_g^{(2)} &= C_A^2 \left(\frac{23}{24} + \frac{11}{18} \pi^2 - \frac{3}{2} \zeta(3) \right) + \frac{1}{2} C_F n_F \\
&\quad - C_A n_F \left(\frac{1}{12} + \frac{\pi^2}{9} \right) - \frac{11}{8} C_A C_F.
\end{aligned} \tag{16}$$

Here, $\zeta(3)$ is the third Riemann function, $n_F = 5$ is the number of active quark flavors, and

$$C_A = N_c = 3, \quad \text{and} \quad C_F = \frac{N_c^2 - 1}{2N_c} = \frac{4}{3} \tag{17}$$

for SU(3) color. The corresponding fermionic coefficients $A_q^{(i)}$ and $B_q^{(i)}$, with $i = 1, 2$ are found in Refs. [24, 26]. The coefficient $A_q^{(3)}$ is available in numerical form [42].

The solution of the linear evolution Eq. (11) may be written in the form

$$W_{gg}(b, Q, x_A, x_B) = e^{-S_g(b, Q)} W_{gg}(b, \frac{c}{b}, x_A, x_B). \tag{18}$$

The function $W_{gg}(b, c/b, x_A, x_B)$ depends on only one momentum variable, $1/b$, and it can be computed in perturbation theory as long as $1/b$ is large enough. All large logarithmic terms from $\ln(c^2/b^2)$ to $\ln(Q^2)$ are resummed to all orders in α_s in the exponential factor, with

$$S_g(b, Q) = \int_{c^2/b^2}^{Q^2} \frac{d\bar{\mu}^2}{\bar{\mu}^2} \left[\ln \left(\frac{Q^2}{\bar{\mu}^2} \right) A_g(\alpha_s(\bar{\mu})) + B_g(\alpha_s(\bar{\mu})) \right]. \tag{19}$$

The appearance of $(c/b)^2$ as the lower limit of integration serves to cut off the non-perturbative region of small Q_T .

The function $W_{gg}(b, c/b, x_A, x_B)$ may be written in factored form as [24, 25]

$$W_{gg}(b, \frac{c}{b}, x_A, x_B) = f_{g/A}(x_A, \mu, \frac{c}{b}) f_{g/B}(x_B, \mu, \frac{c}{b}), \tag{20}$$

where $f_{g/A}$ and $f_{g/B}$ are modified gluon parton distributions

$$f_{g/A}(x_A, \mu, \frac{c}{b}) = \sum_a \int_{x_A}^1 \frac{d\xi}{\xi} \phi_{a/A}(\xi, \mu) C_{a \rightarrow g} \left(\frac{x_A}{\xi}, \mu, \frac{c}{b} \right). \tag{21}$$

Here we see the normal appearance of a factorization scale μ , the scale of factorization between short-distance hard-scattering and the long-distance physics represented by the parton densities. The sum in Eq. (21) runs over all parton types, and $\phi_{a/A}(\xi, \mu)$ is the usual momentum (ξ) distribution of parton a from hadron A at the scale μ . The short-distance coefficient functions are expanded in a perturbative series as

$$C_{a \rightarrow b}\left(z, \mu, \frac{c}{b}\right) = \sum_{n=0} C_{a \rightarrow b}^{(n)}(z, \mu, b) \left(\frac{\alpha_s(\mu)}{\pi}\right)^n. \quad (22)$$

The first two coefficients in the expansion of C are published [37, 38, 39]:

$$\begin{aligned} C_{g \rightarrow g}^{(0)}\left(z, \mu, \frac{c}{b}\right) &= \delta(1-z), \\ C_{i \rightarrow g}^{(0)}\left(z, \mu, \frac{c}{b}\right) &= 0, \\ C_{g \rightarrow g}^{(1)}\left(z, \mu, \frac{c}{b}\right) &= \delta(1-z) \left[C_A \left(\frac{\pi^2}{4} + \frac{5}{4} \right) - \frac{3}{4} C_F \right] \\ &\quad - P_{g \rightarrow g}(z) \ln \left(\frac{\mu b}{c} \right), \\ C_{i \rightarrow g}^{(1)}\left(z, \mu, c/b\right) &= \frac{1}{2} C_F z - P_{i \rightarrow g}(z) \ln \left(\frac{\mu b}{c} \right). \end{aligned} \quad (23)$$

Here i represents a quark or antiquark flavor, and $P_{g \rightarrow g}(z)$ and $P_{i \rightarrow g}(z)$ are leading order parton-to-parton splitting functions,

$$\begin{aligned} P_{g \rightarrow g}(z) &= 2C_A \left[\frac{z}{(1-z)_+} + \frac{(1-z)}{z} + z(1-z) \right] + \frac{11C_A - 2n_F}{6} \delta(1-z), \\ P_{i \rightarrow g}(z) &= C_F \left[\frac{1 + (1-z)^2}{z} \right]. \end{aligned} \quad (24)$$

There is only one momentum scale, $1/b$, involved in the hard-scattering function $W_{gg}(b, c/b, x_A, x_B)$. Therefore, it is natural to choose $\mu = c/b$ in the modified parton densities $f_g(x, \mu, c/b)$ in order to remove the logarithmic terms in Eq. (23). However, this choice is not required. In principle, μ may be any large momentum scale, *e.g.*, Q . This freedom is equivalent to the statement $d/d \ln(\mu^2)[W_{gg}(b, c/b, x_A, x_B)] = 0$ order-by-order in powers of α_s ; or, $d/d \ln \mu^2 f_g(x_A, \mu, c/b) = 0$ order-by-order in α_s for f_g defined in Eq. (21). The μ -dependence in $C_{a \rightarrow g}$ is compensated by the μ -dependence in the parton densities. To order α_s , we derive

$$\frac{d}{d \ln \mu^2} f_g(x, \mu, \frac{c}{b}) = \sum_a \int_x^1 \frac{d\xi}{\xi} \left[\frac{d}{d \ln \mu^2} \phi_a(\xi, \mu) \right] C_{a \rightarrow g}^{(0)}\left(\frac{x}{\xi}, \mu, \frac{c}{b}\right)$$

$$\begin{aligned}
& + \sum_a \int_x^1 \frac{d\xi}{\xi} \phi_a(\xi, \mu) \left[\frac{d}{d \ln \mu^2} C_{a \rightarrow g}^{(1)}\left(\frac{x}{\xi}, \mu, \frac{c}{b}\right) \right] \\
& = \sum_a \int_x^1 \frac{d\xi}{\xi} \left[\frac{d}{d \ln \mu^2} \phi_a(\xi, \mu) \right] \delta_{ag} \delta\left(1 - \frac{x}{\xi}\right) \\
& + \sum_a \int_x^1 \frac{d\xi}{\xi} \phi_{a/A}(\xi, \mu) \left[-\frac{\alpha_s}{2\pi} P_{a \rightarrow g}\left(\frac{x}{\xi}\right) \right] \\
& = 0.
\end{aligned} \tag{25}$$

The last equality follows because both terms on the right-hand-side equal $(d/d \ln \mu^2) \phi_g(x, \mu)$.

For simplicity, we elect to drop the subscript $AB \rightarrow hX$ for the b -space distribution $W_{AB \rightarrow hX}(b, Q, x_A, x_B)$. In its region of validity at small b it takes the factored form

$$W^{\text{pert}}(b, Q, x_A, x_B) = \sigma_{gg \rightarrow hX}^{(0)} \sum_{a,b} \left[\phi_{a/A} \otimes C_{a \rightarrow g} \right] \otimes \left[\phi_{b/B} \otimes C_{b \rightarrow g} \right] \times e^{-S(b, Q)}, \tag{26}$$

where $\otimes$ represents a convolution over parton momentum fractions. Since leading-twist perturbative QCD and normal parton densities are valid only for a hard scale $\mu > \mu_0 \sim 1$ to 2 GeV, we expect naively that $W^{\text{pert}}(b, Q, x_A, x_B)$ will be reliable for $b < 1/\mu_0 \sim 1.0 \text{ GeV}^{-1}$.

To perform the Fourier transform in Eq. (3), we require an expression for $W(b, Q, x_A, x_B)$ that can be used over the entire range of integration in b . To the extent that the region of large b is important in the integrand, we must devise a functional form for $W(b, Q, x_A, x_B)$ that extends into the region of large b , a topic addressed quantitatively in Sec. III. B.

In the CSS formalism, the coefficient functions $C_{i \rightarrow j}$ and the Sudakov form factor $S(b, Q)$ are process dependent. As discussed recently in Ref. [43], it is possible to reorganize the perturbatively calculated coefficient functions $C_{i \rightarrow j}$ and the Sudakov form factor $S(b, Q)$ to make them universal. This universality is achieved if an all orders process-dependent hard part $H_{gg}(\alpha_s(Q))$ is introduced into Eq. (26),

$$W_H^{\text{pert}}(b, Q, x_A, x_B) = \sigma_{gg \rightarrow hX}^{(0)} H_{gg}(\alpha_s(Q)) \sum_{a,b} \left[\phi_{a/A} \otimes C_{a \rightarrow g} \right] \otimes \left[\phi_{b/B} \otimes C_{b \rightarrow g} \right] \times e^{-S(b, Q)}, \tag{27}$$

with $H_{gg}(\alpha_s(Q)) = \sum_n H_{gg}^{(n)}(\alpha_s/\pi)^n$, and the lowest order $H_{gg}^{(0)} = 1$. In analogy with parton distributions, the universal coefficient functions $C_{i \rightarrow j}$ and the Sudakov form factor $S(b, Q)$ can be defined by choosing a “resummation scheme”. The higher order contributions to the hard part, $H_{gg}^{(n)}$, can be calculated perturbatively. Since the reorganization affects only the perturbative part of $W(b, Q, x_A, x_B)$, our approach to extrapolate $W_H^{\text{pert}}(b, Q, x_A, x_B)$ into the nonperturbative large b region, discussed in Sec. III. B, could also be used to calculate the Q_T distribution in this modification of the CSS formalism.

III. ROLE OF THE REGION OF LARGE IMPACT PARAMETER

A. Suppressed role of the region of large b at large $\sqrt{S}$

Prior to presenting alternative expressions for the extrapolation of $W(b, Q, x_A, x_B)$ into the region of large b , we emphasize one important property of the b -space resummation formalism: the resummed exponential factor $\exp[-S(b, Q)]$ suppresses the b -integrand in Eq. (3) when b is larger than $1/Q$. Therefore, when $Q \gg \mu_0$, the Fourier transform is dominated by a region of b much smaller than $1/\mu_0$, and the calculated Q_T distribution is insensitive to the non-perturbative information at large b .

Saddle-point methods are used in Refs. [24, 44] to show that for large enough Q , the Fourier transform in Eq. (3) is dominated by an impact parameter

$$b_{\text{SP}} \simeq \frac{1}{\Lambda_{\text{QCD}}} \left(\frac{\Lambda_{\text{QCD}}}{Q} \right)^\lambda, \quad (28)$$

where $\lambda = 2A^{(1)}/(2A^{(1)} + \beta_0) \approx 0.61$ and ≈ 0.41 , for gluonic and fermionic processes, respectively, for $n_f = 5$ quark flavors. This equation shows that the momentum scale corresponding to the saddle point, $1/b_{\text{SP}}$, should be within the perturbative region if Q is large enough. In Ref. [32], a more complete expression is derived for b_{SP} that takes into account the full b dependence of $W_{ij}(b, c/b, x_A, x_B)$.

The saddle point at $Q_T = 0$ is determined from the differential equation

$$\frac{d}{db} \ln \left(b e^{-S(b, Q)} \right)_{b=b_0} + \frac{d}{db} \ln \left(\sum_{ij} \sigma_{ij \rightarrow hX}(Q) W_{ij}(b, \frac{c}{b}, x_A, x_B) \right)_{b=b_0} = 0. \quad (29)$$

If $W_{ij}(b, c/b, x_A, x_B)$ has a weak dependence on b near b_0 , the second term in Eq. (29) can be neglected, and the first term yields $b_0 \approx b_{\text{SP}}$. However, as we now show, the b -dependence of $W_{ij}(b, c/b, x_A, x_B)$ is directly proportional to the evolution of the modified parton distributions.

The second term on the left-hand side of Eq. (29) can be expressed as

$$\frac{d}{db} \ln \left(\sigma_{gg}(Q) W_{gg}(b, \frac{c}{b}, x_A, x_B) \right) = \frac{d}{db} \left(\ln f_{g/A}(x_A, \mu, \frac{c}{b}) + \ln f_{g/B}(x_B, \mu, \frac{c}{b}) \right), \quad (30)$$

and

$$\frac{d}{db} f_{g/A}(x_A, \mu, \frac{c}{b}) = \frac{1}{b} \sum_a \int_{x_A}^1 \frac{d\xi}{\xi} \phi_{a/A}(\xi, \mu) \left[\frac{d}{d \ln b} C_{a \rightarrow g}(\frac{x_A}{\xi}, \mu, \frac{c}{b}) \right]$$

$$\begin{aligned}
&\approx \frac{1}{b} \sum_a \int_{x_A}^1 \frac{d\xi}{\xi} \phi_{a/A}(\xi, \mu) \left[-\frac{\alpha_s}{\pi} P_{a \rightarrow g}\left(\frac{x_A}{\xi}\right) \right] \\
&\approx -\frac{2}{b} \frac{d}{d \ln \mu^2} \phi_{g/A}(x_A, \mu) .
\end{aligned} \tag{31}$$

The derivative $(d/d \ln \mu) \phi(x, \mu)$ is typically positive (negative) for $x < x_0 \sim 0.1$ ($x > x_0$), and the evolution is very steep when x is far from x_0 . Correspondingly, the second term in Eq. (29) should be important when the relevant values of $x_A \sim Q/\sqrt{S}$ and $x_B \sim Q/\sqrt{S}$ are much smaller (or much greater) than x_0 . At the LHC, $x_A \sim x_B \sim 0.009$ for $m_h = 125$ GeV.

FIG. 1: The function $S(b, Q)$ for Higgs boson production in gluon-gluon fusion at (a) $Q = m_h = 125$ GeV and (b) $m_h = M_Z$ as a function of impact parameter b . We show results for different orders of accuracy in the perturbative expansions of the functions A_g and B_g . The dotted curve is obtained with only the first order contributions $A_g^{(1)}$ and $B_g^{(1)}$ retained. For the dashed curve, we include $A_g^{(2)}$ in addition, and for the solid curve, we keep all terms through $A_g^{(2)}$ and $B_g^{(2)}$ in Eq. (16).

The first term alone in Eq. (29) is a decreasing function of b . The derivative vanishes at $b = b_{\text{SP}}$ producing a first approximation for the saddle point solution, Eq. (28). The negative sign in Eq. (31), and the fact that the number of small x partons increases when the scale μ increases, mean that the second term in Eq. (29) is negative when x_A and x_B are smaller

than the typical x_0 . The full solution to Eq. (29) provides a saddle point that is less than the first approximation $b = b_{\text{SP}}$. (Conversely, at fixed-target energies where the typical x_A and x_B are greater than x_0 , the typical b is greater than b_{SP} .) The numerical value for the saddle point depends strongly on $\sqrt{S}$, improving the predictive power of b -space resummation at large energies. When $Q_T > 0$, the Bessel function $J_0(z = Q_T b)$ further suppresses the large b region of the b -integration. The suppression is greater for greater Q_T , and the b -space resummation formalism is expected to work progressively better for larger Q_T .

In the remainder of this subsection, we present figures that illustrate the b dependences of the Sudakov function $S(b, Q)$ and of the factor $bW(b, Q)$ in the integrand of Eq. (3), and we comment on their physical implications. The Sudakov function depends only on Q and on the perturbatively calculable functions A_g and B_g , Eqs. (15 - 19). Selecting $Q = m_h = 125$ GeV, we show the behavior of $S(b, m_h)$ in Fig. 1. The function has a pronounced minimum at very small b , $b \sim 0.02$ GeV $^{-1}$. Since it is $\exp[-S(b, Q)]$ that enters the integrand, Fig. 1 shows that the Sudakov factor strongly suppresses both the large and small regions of b . It is instructive to examine the relative importance of next-to-leading order contributions in the functions A_g and B_g . As shown in the figure, it may be sufficient at very small b to retain only the first-order contributions, $A_g^{(1)}$ and $B_g^{(1)}$. However, the second-order contributions, both $A_g^{(2)}$ and $B_g^{(2)}$, are of growing relevance as b grows. The larger Sudakov function at large b in next-to-leading order means that the region of small Q_T is more suppressed, resulting in a shift of the peak of the distribution $d\sigma/dy dQ_T$ to somewhat larger Q_T at higher orders. The large change associated with $A_g^{(2)}$ may be understood because A_g in Eq. (19) is multiplied by $\ln(Q^2)$. It is possible that inclusion of $A_g^{(3)}$, once it is known, will produce important effects. A comparison of the results in Figs. 1(a) and (b) shows that the Sudakov function is peaked more narrowly at greater m_h . The suppression of the region of large b is more pronounced for larger m_h , again influencing a shift of the peak of the distribution $d\sigma/dy dQ_T$ to somewhat larger Q_T as m_h is increased.

To examine the differences between Z production and Higgs boson production, we show in Fig. 2 the results appropriate for Z boson production, with $Q = M_Z = 91.187$ GeV. The second-order fermionic function $B_q^{(2)}$ plays a much less significant role in Z production than does the gluonic function $B_g^{(2)}$ in Higgs boson production. Comparison of Figs. 1(b) and 2 shows that the gluonic Sudakov function is much larger than its quark counterpart, but the curves are similar in shape otherwise. At $b = 1$, the ratio is about 2.5. The fact that

FIG. 2: The function $S(b, Q)$ for Z boson production in as a function of impact parameter b . We show results for different orders of accuracy in the perturbative expansions of the functions A_g and B_g .

the gluonic A_g and B_g functions are larger than their fermionic counterparts A_q and B_q is related to the differences in the values of the structure constants C_A and C_F . The larger color factor for gluons means that gluons radiate more readily. There will be more gluonic showering and correspondingly more suppression of the region of large b (*i.e.*, small Q_T) when gluonic subprocesses are dominant. Greater suppression of the region of large b means that perturbation theory will have greater predictive power and resummed calculations will be more reliable for gluonic processes.

The all-orders resummed b -space function $W(b, Q)$, Eq. (26), depends on the choice of parton densities. We use the CTEQ5M set [45]. In Fig. 3, we show $bW(b, Q)$ as a function of b at the energy of the LHC for two choices of the Higgs boson mass. This function is peaked sharply near $b \sim 0.05 \text{ GeV}^{-1}$ (*c.f.*, $Q_T \sim 20 \text{ GeV}$) well within the region of applicability of perturbative QCD. The function has essentially no support for $b > 0.5 \text{ GeV}^{-1}$. We expect, therefore, that the non-perturbative input at large b will play a negligible role in Higgs boson production at LHC energies. Comparison of Figs. 3(a) and (b) demonstrates that the

FIG. 3: The all-orders b -space resummed function $bW(b, Q)$ for Higgs boson production in gluon-gluon fusion at $\sqrt{S} = 14 \text{ TeV}$ for (a) $Q = m_h = 125 \text{ GeV}$ and (b) $m_h = M_Z$ as a function of impact parameter b .

function is peaked somewhat more narrowly at larger m_h .

We present Fig. 4 to illustrate the difference in the resummed b space distributions for Higgs boson and Z boson production. In Figs. 3(b) and 4, we select the same mass $Q = M_Z$ and collider energy $\sqrt{S}$. The function peaks near $b \sim 0.12 \text{ GeV}^{-1}$ for Z production, at about twice the value for Higgs boson production. The peak in the Q_T distribution will therefore occur at a smaller value of Q_T for Z production than for Higgs boson production. The significantly narrower distribution in b in the Higgs boson case is a reflection of the larger gluonic Sudakov factor. Predictions for the Q_T distribution of Higgs boson production are therefore expected to be less sensitive to non-perturbative physics than those for Z production, even if $m_h = M_Z$. (We note that at LHC energies, the typical values of x in the parton densities are $\sim M_Z/\sqrt{S}$ and $\sim m_h/\sqrt{S}$. Even for $m_h = 200 \text{ GeV}$, $x < 2 \times 10^{-2}$. Therefore, production at the LHC is influenced by the behavior of parton densities at small x , not at large x where the more rapid fall-off of the gluon density might otherwise make the Q_T distribution for Higgs boson production decrease more rapidly than that for Z production.)

FIG. 4: The all-orders b -space resummed function $bW(b, Q)$ for Z boson production at $\sqrt{S} = 14 \text{ TeV}$ as a function of impact parameter b .

B. Extrapolation into the region of large- b

The perturbatively resummed function $W(b, Q, x_A, x_B)$ in Eq. (3) is reliable only when b is small. An extrapolation into the region of large b is necessary in order to complete the Fourier transform in Eq. (3). In this section, we summarize different forms used in the literature for this extrapolation. The functional form of Qiu and Zhang [32] has the desirable property that it separates cleanly the perturbative prediction at small b from non-perturbative physics in the large b region.

In Ref. [24], a variable b_* is introduced along with a non-perturbative function $F^{NP}(b, Q, x_A, x_B)$,

$$W^{\text{CSS}}(b, Q, x_A, x_B) \equiv W^{\text{pert}}(b_*, Q, x_A, x_B) F^{NP}(b, Q, x_A, x_B), \quad (32)$$

where $b_* = b / \sqrt{1 + (b/b_{\text{max}})^2} < b_{\text{max}} = 0.5 \text{ GeV}^{-1}$; F^{NP} has a Gaussian-like dependence on b . The assumed non-perturbative distribution F^{NP} has the functional form [24]

$$F_{ij}^{NP}(b, Q, x_A, x_B) = \exp \left[-\ln(Q^2 b_{\text{max}}^2) g_1(b) - g_{i/A}(x_A, b) - g_{j/B}(x_B, b) \right]. \quad (33)$$

The $\ln(Q^2)$ dependence is a prediction of the renormalization group equations. The functions $g_1(b)$, $g_{i/A}(x_A, b)$, and $g_{j/B}(x_B, b)$ are non-perturbative and assumed to vanish as $b \rightarrow 0$. The predictive power of the CSS formalism relies on the derived Q^2 dependence and the universality of the functions F_{ij}^{NP} , fitted at one energy and used elsewhere.

Davies and Stirling (DS) proposed a simpler form for F^{NP} [26]

$$F_{DS}^{NP}(b, Q, x_A, x_B) = \exp \left[-b^2 (g_1 + g_2 \ln(Qb_{\max}/2)) \right], \quad (34)$$

where g_1 and g_2 are flavor-independent fitting parameters. To incorporate possible $\ln(\tau)$ dependence, $\tau = Q^2/S = x_A x_B$, Ladinsky and Yuan (LY) introduced an additional parameter g_3 in a modified functional form [28]

$$F_{LY}^{NP}(b, Q, x_A, x_B) = \exp \left[-b^2 (g_1 + g_2 \ln(Qb_{\max}/2)) - b g_1 g_3 \ln(100x_A x_B) \right]. \quad (35)$$

Similar to the DS parameterization, no flavor dependence is present. Landry, Brock, Ladinsky, and Yuan (LBLEY) reported a global fit to the low energy Drell-Yan data as well as high energy W and Z data using both DS and LY parameterizations [33].

To preserve the predictive power of perturbative calculations, it is important that $W^{\text{CSS}}(b, Q, x_A, x_B)$ be consistent with the perturbatively calculated $W^{\text{pert}}(b, Q, x_A, x_B)$ when $b < b_{\max}$. However, use of the b_* variable necessarily alters the perturbatively calculated b -space distribution even within the perturbative region [32]. This alteration can be significant depending on the choice of the parametrization of F^{NP} . In the last subsection (c.f., Figs. 3 and 4), we argue that the Q_T distributions of W , Z , and Higgs boson production at collider energies should not be sensitive to the large b tail of the spectrum. Any significant dependence on the fitting parameters would cast doubt on the predictive power of the b -space resummation formalism.

In Ref. [32], Qiu and Zhang introduce a new extrapolation

$$W(b, Q, x_A, x_B) = \begin{cases} W^{\text{pert}}(b, Q, x_A, x_B) & b \leq b_{\max} \\ W^{\text{pert}}(b_{\max}, Q, x_A, x_B) F^{NP}(b, Q; b_{\max}) & b > b_{\max}. \end{cases} \quad (36)$$

This expression manifestly preserves the QCD resummed b -space distribution in the perturbative region at small b . The authors also motivate the adoption of a new non-perturbative function in the region of large b :

$$F^{NP} = \exp \left\{ -\ln\left(\frac{Q^2 b_{\max}^2}{c^2}\right) \left[g_1 \left((b^2)^\alpha - (b_{\max}^2)^\alpha \right) + g_2 (b^2 - b_{\max}^2) \right] - \bar{g}_2 (b^2 - b_{\max}^2) \right\}. \quad (37)$$

The term proportional to $(b^2)^\alpha$, with $\alpha < 1/2$, corresponds to a direct extrapolation of the resummed $W^{\text{pert}}(b, Q, x_A, x_B)$. The parameters, g_1 and α are fixed in relation to W^{pert} by the requirement that the first and second derivatives of $W(b, Q, x_A, x_B)$ be continuous at $b = b_{\text{max}}$. Dependence on x_A and x_B is included in the parameters g_1 and α . The terms proportional to b^2 correspond to inverse-power corrections to the evolution equation. Power corrections from soft gluon showers are the origin of the g_2 term, and non-vanishing intrinsic transverse momenta of the incident partons lead to the $\bar{g}_2$ term. The values of g_2 and $\bar{g}_2$ are unknown and must be obtained from fits to data.

FIG. 5: Ratios of the functions $bW(b, Q)$. Comparisons are shown of (a) the DS parametrization and (b) the LY choice with respect to the function we use in this paper. The solid lines show the comparisons for Z production at the energy of the Fermilab Tevatron, $\sqrt{S} = 1.8$ TeV. The dashed and dotted lines show the ratios for Higgs boson production at the LHC.

In Fig. 5 we present ratios of the functions $bW(b, Q)$ in use by different groups. In Fig. 5(a), the numerator is the two-parameter form of Davies and Stirling, whereas in Fig. 5(b) it is the three-parameter functional form adopted by Ladinsky and Yuan, Eqs. (32) and (35). However, in both cases we use the updated parameters of Landry *et al* and the CTEQ5M parton densities. The denominator in the ratios is the Qiu and Zhang function we

use in this paper, Eqs. (36) and (37), with $b_{\max} = 0.5$, $g_2 = 0$, and $\bar{g}_2 = 0$. For Z production at the energy of the Tevatron, the ratios do not deviate from 1 by more than 20% as long as $b < 0.5$, as might be expected because all groups provide acceptable fits to data. However, very significant deviations from 1 are evident at the energy of the LHC, notably in the region $b < 0.5$ where purely perturbative physics should be dominant. The deviations reach 100% for $b \sim 0.4$. This comparison shows explicitly the influence within the purely perturbative region of the use of the variable b_* and the nonperturbative function F^{NP} in Eq. (32).

Figure 5 shows that the deviations from the perturbatively calculated $W^{\text{pert}}(b, Q)$ depend strongly on the collision energy $\sqrt{S}$. This energy dependence is an artifact of the use of the variable b_* . Since $b_* < b$ for all $b \neq 0$, the shifted b -space distribution $W^{\text{pert}}(b_*, Q) < W^{\text{pert}}(b, Q)$ for values of b smaller than the location of saddle point, and $W^{\text{pert}}(b_*, Q) > W^{\text{pert}}(b, Q)$ for b larger than the saddle point. The magnitude of the difference between the $W^{\text{pert}}(b_*, Q)$ and $W^{\text{pert}}(b, Q)$ depends on the shape of $W^{\text{pert}}(b, Q)$. When $\sqrt{S}$ increases, $W^{\text{pert}}(b, Q)$ becomes narrower, and its much steeper behavior leads to a larger deviation of $W^{\text{pert}}(b_*, Q)$ from $W^{\text{pert}}(b, Q)$. The use of either the DS or the LY parameterizations in $W^{\text{CSS}}(b, Q)$, Eq. (32), leads to a reduction in the region $b < 0.2$ and strong enhancement in the region $b > 0.2$. Once the Fourier transform is made to Q_T space, the net effects of these two differences are a slight shift to smaller Q_T in the location of the predicted maximum of the distribution $d\sigma/dy dQ_T$ and reduction in the magnitude of the peak value.

IV. EXPRESSIONS FOR THE FIXED-ORDER CONTRIBUTIONS IN PERTURBATIVE QCD

Working at fixed-order in QCD perturbation theory [19, 20, 21, 22], one can express the differential cross section for Higgs boson production in the form of a convolution

$$\begin{aligned} \frac{d\sigma_{AB \rightarrow hX}^{(\text{pert})}}{dQ^2 dy dQ_T^2} &= \sigma_{gg \rightarrow hX}^{(0)} \sum_{ab} \int_{x_A}^1 \frac{d\xi_A}{\xi_A} \int_{x_B}^1 \frac{d\xi_B}{\xi_B} \phi_{a/A}(\xi_A, \mu) \phi_{b/B}(\xi_B, \mu) \\ &\quad \times H_{ab \rightarrow hX}(Q_T, Q, \frac{x_A}{\xi_A}, \frac{x_B}{\xi_B}, \alpha_s(\mu), \mu). \end{aligned} \quad (38)$$

In this expression, $\sigma_{gg \rightarrow hX}^{(0)}$ is the cross section given in Eq. (8). The functions $\phi_{a/A}(x_A, \mu)$ and $\phi_{b/B}(x_B, \mu)$ are probabilities that incident partons a and b from hadrons A and B carry fractional light-cone momenta x_A and x_B , respectively, at factorization scale μ . The

parton level hard-scattering function $H_{ab \rightarrow hX}(Q_T, Q, x_A/\xi_A, x_B/\xi_B, \alpha_s(\mu), \mu)$ is expanded in a power-series in the strong coupling strength α_s

$$H_{ab \rightarrow hX} = \sum_{n=0} H_{ab \rightarrow hX}^{(n)} \left(\frac{\alpha_s(\mu)}{\pi} \right)^n. \quad (39)$$

The lowest order contribution ($n = 0$), $gg \rightarrow h$ comes from the top-quark loop, and, in the absence of partonic intrinsic transverse momentum, it yields a distribution that is a δ -function in transverse momentum Q_T

$$H_{gg}^{(0)} = \delta \left(1 - \frac{x_A}{\xi_A} \right) \delta \left(1 - \frac{x_B}{\xi_B} \right) \delta^2(Q_T). \quad (40)$$

At first-order in α_s , there are virtual loop-corrections to the subprocess $gg \rightarrow h$ along with contributions in which two partons interact to produce a parton plus the Higgs boson. Labeling these 2-to-2 contributions by the tree-subprocesses, we write the functions $H_{ab \rightarrow hX}^{(1)}$ in terms of partonic Mandelstam variables $\hat{s}$, $\hat{t}$, and $\hat{u}$ as [19]

gluon-gluon $gg \rightarrow hg$:

$$H_{gg}^{(1)} = \frac{1}{2\pi} C_A \left[\frac{\hat{s}^4 + \hat{t}^4 + \hat{u}^4 + Q^8}{\hat{s} \hat{t} \hat{u} Q^2} \right] \delta(\hat{s} + \hat{t} + \hat{u} - Q^2), \quad (41)$$

gluon-quark(antiquark) $gq \rightarrow hq$ ($g\bar{q} \rightarrow h\bar{q}$):

$$H_{gq}^{(1)} = \frac{1}{2\pi} C_F \left[\frac{\hat{s}^2 + \hat{u}^2}{-\hat{t} Q^2} \right] \delta(\hat{s} + \hat{t} + \hat{u} - Q^2), \quad (42)$$

quark(antiquark)-gluon $qg \rightarrow hq$ ($\bar{q}g \rightarrow h\bar{q}$):

$$H_{qg}^{(1)} = \frac{1}{2\pi} C_F \left[\frac{\hat{s}^2 + \hat{t}^2}{-\hat{u} Q^2} \right] \delta(\hat{s} + \hat{t} + \hat{u} - Q^2), \quad (43)$$

and the s-channel *quark-antiquark* subprocess $q\bar{q} \rightarrow hg$:

$$H_{q\bar{q}}^{(1)} = \frac{1}{2\pi} \left(\frac{C_F}{C_A} (N^2 - 1) \right) \left[\frac{\hat{t}^2 + \hat{u}^2}{\hat{s} Q^2} \right] \delta(\hat{s} + \hat{t} + \hat{u} - Q^2). \quad (44)$$

The first-order contributions from gg , gq , and $q\bar{q}$ scattering are all singular as $Q_T \rightarrow 0$. Following convention, we use the word “asymptotic” to designate the terms that are at least as singular as Q_T^{-2} . This asymptotic contribution may be written in analogy to Eq. (38) as the convolution

$$\begin{aligned} \frac{d\sigma_{AB \rightarrow hX}^{(\text{asym})}}{dQ^2 dy dQ_T^2} &= \sigma_{gg \rightarrow hX}^{(0)} \sum_{ab} \int_{x_A}^1 \frac{d\xi_A}{\xi_A} \int_{x_B}^1 \frac{d\xi_B}{\xi_B} \phi_{a/A}(\xi_A, \mu) \phi_{b/B}(\xi_B, \mu) \\ &\quad \times w_{ab \rightarrow hX}(Q_T, Q, \frac{x_A}{\xi_A}, \frac{x_B}{\xi_B}, \alpha_s(\mu), \mu). \end{aligned} \quad (45)$$

Expanded in a power series in α_s , the asymptotic partonic hard part $w_{ab \rightarrow hX}$ becomes

$$w_{ab \rightarrow hX} = \sum_{n=1} w_{ab \rightarrow hX}^{(n)} \left(\frac{\alpha_s(\mu)}{\pi} \right)^n. \quad (46)$$

The lowest order asymptotic contributions ($n = 0$) vanish for $Q_T > 0$,

$$w_{ab}^{(0)} = 0. \quad (47)$$

Categorizing the first-order contributions as before, we write the asymptotic forms as *gluon-gluon*:

$$w_{gg}^{(1)} = \frac{1}{2\pi} \frac{1}{Q_T^2} \left\{ 2\delta(1-z_A)\delta(1-z_B) \left[A_g^{(1)} \log\left(\frac{Q^2}{Q_T^2}\right) + B_g^{(1)} \right] \right. \\ \left. + \delta(1-z_A) P_{g \rightarrow g}(z_B) + \delta(1-z_B) P_{g \rightarrow g}(z_A) \right\}, \quad (48)$$

where

$$z_A = \frac{x_A}{\xi_A}, \quad \text{and} \quad z_B = \frac{x_B}{\xi_B}. \quad (49)$$

The forms are simpler for the other subprocesses.

gluon-quark(antiquark):

$$w_{gq}^{(1)} = \frac{1}{2\pi} \frac{1}{Q_T^2} \left\{ \delta(1-z_A) P_{q \rightarrow g}(z_B) \right\}, \quad (50)$$

quark(antiquark)-gluon:

$$w_{qg}^{(1)} = \frac{1}{2\pi} \frac{1}{Q_T^2} \left\{ \delta(1-z_B) P_{q \rightarrow g}(z_A) \right\}, \quad (51)$$

and *quark-antiquark*:

$$w_{q\bar{q}}^{(1)} = 0. \quad (52)$$

As discussed in Sec. II, resummation treats only the parts of the fixed-order QCD expressions that are at least as singular as Q_T^{-2} in the limit $Q_T \rightarrow 0$. The remainder is

$$\frac{d\sigma_{AB \rightarrow hX}^{(Y)}}{dQ^2 dy dQ_T^2} = \sigma_{gg \rightarrow hX}^{(0)} \sum_{ab} \int_{x_A}^1 \frac{d\xi_A}{\xi_A} \int_{x_B}^1 \frac{d\xi_B}{\xi_B} \phi_{a/A}(\xi_A, \mu) \phi_{b/B}(\xi_B, \mu) \\ \times R_{ab \rightarrow hX}(Q_T, Q, \frac{x_A}{\xi_A}, \frac{x_B}{\xi_B}, \alpha_s(\mu), \mu). \quad (53)$$

As a power-series expansion in α_s , the partonic hard part for the remainder term is

$$R_{ab \rightarrow hX} = \sum_{n=0} R_{ab \rightarrow hX}^{(n)} \left(\frac{\alpha_s(\mu)}{\pi} \right)^n, \quad (54)$$

where

$$R_{ab \rightarrow hX}^{(n)} = H_{ab \rightarrow hX}^{(n)} - w_{ab \rightarrow hX}^{(n)}. \quad (55)$$

In our numerical work presented in Sec. V, we use order α_s expressions for $H_{ab \rightarrow hX}^{(n)}$. In subsequent investigations, one might incorporate the NLO results [21, 22].

V. PREDICTIONS

In this section we present our predictions for the transverse momentum distribution of Higgs boson production in proton-proton collisions at the LHC energy $\sqrt{S} = 14$ TeV. We provide results at both fixed rapidity $y = 0$ and for the cross section integrated over the rapidity range $|y| \leq 2.4$. To illustrate interesting differences, we also show our results for Z boson production at the same energy [34]. Our predictions are based on Eqs. (2), (3), (26), and (53). We employ expressions for the parton-level hard-scattering functions valid through first-order in α_s , Eqs. (40) - (44), with the asymptotic forms Eqs. (47) - (52). For A_g and B_g in the Sudakov factor, Eq. (19), we take the expansion valid through second order ($n = 2$), Eq. (16). For the coefficient functions in the modified parton densities, we use the expansion through $n = 1$, Eq. (23). (Our results are therefore consistently at next-to-leading-logarithm (NLL) accuracy). We use a next-to-leading order form for $\alpha_s(\mu)$ and next-to-leading order normal parton densities $\phi(x, \mu)$ [45]. In the fixed-order perturbative expressions that enter the “Y” function, we select a fixed renormalization/factorization scale $\mu = \kappa \sqrt{m_h^2 + Q_T^2}$, with $\kappa = 0.5$. For the resummed term, we take as our central value $\mu = c/b$, with $c = 2e^{-\gamma_E}$. To show sensitivity to the choice of μ , we also compute cross sections with the choices $\mu = 0.5m_h$ and $\mu = 2m_h$.

The extrapolation into the non-perturbative region of large b is accomplished with Eqs. (36) and (37). As remarked before, the parameters g_1 and α in Eq. (37) are fixed in relation to W^{pert} by the requirement that the first and second derivatives of $W(b, Q, x_A, x_B)$ be continuous at $b = b_{\text{max}} = 0.5 \text{ GeV}^{-1}$. Since, as shown in Sec. III A, there is little sensitivity to the region of large b , we adopt for most of our results the values $g_2 = 0$ and $\bar{g}_2 = 0$ in Eq. (37). However, to demonstrate the insensitivity numerically, we also present results for other choices of b_{max} , g_2 , and $\bar{g}_2$.

FIG. 6: Differential cross section $d\sigma/dy dQ_T$ for Higgs boson production at $\sqrt{s} = 14$ TeV and fixed rapidity $y = 0$ with (a) $Q = M_Z$, (b) $Q = m_h = 125$ GeV, (c) $Q = m_h = 150$ GeV, and (d) $Q = m_h = 200$ GeV, as a function of transverse momentum Q_T . The total prediction is shown as a solid line. In (a) and (c), the fixed-order perturbative calculation is shown as a dashed line and its asymptotic limit as a dotted line. In (b) and (d), the contribution from the remainder Y term is shown as a dashed line.

In the limit $Q_T \rightarrow 0$, sub-dominant singularities may produce a mismatch [24] between the complete fixed-order expressions in Eqs. (41) - (44) and their asymptotic forms in Eqs. (48) - (52). Sub-leading divergences could drive the difference toward a negative infinity as $Q_T \rightarrow 0$. The “Y” term is not large in the region of small Q_T , but the singularity in the limit $Q_T \rightarrow 0$ can pull the sum in Eq. (2) to negative values in the region of very small Q_T . There are various possible remedies for this difficulty, including introduction of an off-set in Q_T in the “Y” function. In our numerical work, we use a parameter $Q_T^{\min}$, replacing Q_T in the “Y” function only by $\sqrt{Q_T^2 + (Q_T^{\min})^2}$. In keeping with CSS, we select $Q_T^{\min} = 0.3$ GeV as our central value and show the sensitivity of results to choices ranging from $Q_T^{\min} = 0$ to $Q_T^{\min} = 0.5$ GeV.

The Bessel function in the integrand of Eq. (3) is an oscillatory function, and a high degree of numerical accuracy is necessary to ensure accurate cancellations. The number of oscillations depends strongly on the value of Q_T . When $b \in (0, 2)$ GeV⁻¹, the number of times $J_0(Q_T b)$ crosses zero is 0, 6, 63, and 127 for $Q_T = 1, 10, 100$, and 200 GeV, respectively. Following Qiu and Zhang, we use an integral form for the Bessel function

$$J_0(z) = \frac{1}{\pi} \int_0^\pi \cos(z \sin(\theta)) d\theta. \quad (56)$$

Overall numerical accuracy is controlled by improving the accuracy of the integration in Eq. (56).

A. Q_T distributions for Higgs boson and Z production

We display our predicted Q_T distributions for Higgs boson production at the LHC in Figs. 6 and 7, respectively. In Fig. 6, we show $d\sigma/dy dQ_T$ as a function of Q_T at fixed rapidity $y = 0$, whereas in Fig. 7, we show the Q_T distributions for rapidity integrated over the interval $|y| < 2.4$. (The choice $|y| < 2.4$ is motivated by the expected acceptance of the LHC detectors for photons [7].) We present results for four choices of mass of the Higgs boson, values that span the range of present interest in the SM, $m_h = M_Z = 91.187$ GeV, $m_h = 125$ GeV, $m_h = 150$ GeV (where the WW^* decay channel is dominant), and $m_h = 200$ GeV (above both WW and ZZ decay thresholds). In all cases, the solid lines represent the total prediction, Eq. (2). In Figs. 6(a) and (c), as well as in Figs. 7(a) and (c), we also show the fixed-order purely perturbative result and its $Q_T \rightarrow 0$ asymptotic form. In Figs. 6(b) and

(d), as well as in Figs. 7(b) and (d), we show instead the contribution from the fixed-order remainder “Y” term.

In Figs. 6(a) and (c), we observe the divergence as $Q_T \rightarrow 0$ of the fixed-order purely perturbative result and the expected numerical equality of the purely perturbative result and its $Q_T \rightarrow 0$ asymptotic form at small Q_T . The asymptotic form falls away more rapidly with Q_T . Figures 6(b) and (d) demonstrate that the total prediction, Eq. (2), is clearly dominated by the all-orders resummed term for $Q_T \leq Q$. At larger Q_T , the Y term is comparable in size. In the expression for Y, we use the order- α_s QCD expressions. Next-to-leading order contributions tend to alter theoretical predictions, and, correspondingly, we would expect that our predictions would change somewhat for $Q_T > Q$ if higher order contributions are included.

The resummed result (labeled “total”) makes a smooth transition to the fixed-order perturbative result near or just above $Q_T = Q$, for all Q , without need of a supplementary matching procedure. With all Q_T distributions extended to $Q_T = 100$ GeV, our implementation of the resummation formalism works smoothly throughout the Q_T region even for the distributions differential in rapidity, $d\sigma/dy dQ_T$. The transition from the resummed distribution to the fixed-order perturbative contribution is continuous and less ambiguous than is sometimes seen in the literature.

We note that the resummed results for Higgs boson production begin to fall below the fixed-order perturbative expectations when Q_T exceeds Q . This effect is likely due to the mismatch at order α_s between the resummed term and the asymptotic term. A similar effect is not seen in our predictions for Z boson production where the fermionic coefficient $A_q^{(1)}$ is smaller than the gluonic coefficient $A_g^{(1)}$. The fixed-order result should provide the correct theoretical answer for $Q_T \sim Q$ (and above) where only one large momentum scale is present and large logarithmic effects proportional to $\ln(Q/Q_T)$ are insignificant. We adopt the fixed-order result as our best estimate of the theoretical prediction wherever it is larger than the resummed result in the region $Q_T > Q$.

We display our predicted Q_T distributions for Z boson production at the LHC in Figs. 8. The resummed distributions are very smooth functions of Q_T over the full range shown and they converge without discontinuity with the fixed-order perturbative results above $Q_T = M_Z$. No supplementary matching is employed.

Two points are evident in the comparison of Z boson and Higgs boson production, with

FIG. 7: Differential cross section $d\sigma/dQ_T$ for Higgs boson production at $\sqrt{S} = 14$ TeV with rapidity integrated over the interval $|y| < 2.4$ with (a) $Q = M_Z$, (b) $Q = m_h = 125$ GeV, (c) $Q = m_h = 150$ GeV, and (d) $Q = m_h = 200$ GeV, as a function of transverse momentum Q_T . The total prediction is shown as a solid line. In (a) and (c), the fixed-order perturbative calculation is shown as a dashed line and its asymptotic limit as a dotted line. In (b) and (d), the contribution from the remainder Y term is shown as a dashed line.

$m_h = M_Z$. The peak in the Q_T distribution occurs at a smaller value of Q_T for Z production. At $y = 0$, the curve peaks at $Q_T \sim 4.8$ GeV for Z production and at $Q_T \sim 10$ GeV for Higgs boson production. Second, the distribution is narrower for Z production, falling to half its maximum by $Q_T \sim 16$ GeV, whereas the half-maximum for Higgs production is not reached until $Q_T \sim 30$ GeV. Technically, both differences are a direct reflection of the differences in the functions $bW(b, Q)$ discussed in Sec. III A. The b -space distribution is narrower for Higgs boson production and peaks at smaller b . Correspondingly, since $Q_T \sim 1/b$, the Q_T distribution is broader and peaks at larger Q_T . The physics behind this important difference is that the larger QCD color factors produce more gluonic showering in the glue-gluon scattering subprocess that dominates inclusive Higgs boson production than in the fermionic subprocesses relevant for Z production. After all-orders resummation, the enhanced showering suppresses the large- b (small Q_T) region more effectively for Higgs boson production.

FIG. 8: Differential cross section $d\sigma/dy dQ_T$ as a function of transverse momentum Q_T for Z boson production at $\sqrt{S} = 14$ TeV and (a) fixed rapidity $y = 0$ and (b) $|y| < 2.4$. Shown are the total prediction as a solid line, the fixed-order perturbative calculation as a dashed line, and the asymptotic limit as a dotted line.

Comparison of the predicted Q_T distributions for Higgs boson production at different masses of the Higgs boson shows that the peak of the distribution shifts to greater Q_T as m_h grows and that the distribution broadens somewhat. At $y = 0$, the peaks are centered at about $Q_T = 10, 11.5, 12.6$, and 14.4 GeV for $m_h = M_Z, 125, 150$, and 200 GeV, respectively. The mass dependence for both Higgs and Z boson production is illustrated in Fig. 9. For Z^* boson masses above the physical value M_Z we assume that the production model is unchanged except for the difference in mass of the Z^* . The peak position at $y = 0$ is at 5.5 GeV for $M_{Z^*} = 200$ GeV.

FIG. 9: Location of the peaks of the transverse momentum distributions for Higgs boson and Z^* boson production as a function of Higgs boson mass at $\sqrt{S} = 14$ TeV. For Higgs boson production we show results at fixed rapidity $y = 0$ and for y integrated over the interval $|y| \leq 2.4$.

The change of the Q_T distribution with m_h can also be represented quantitatively with plots of the mean value $\langle Q_T \rangle$ and of the root-mean-square $\langle Q_T^2 \rangle^{\frac{1}{2}}$, shown in Fig. 10. Because of the long tail of the distribution $d\sigma/dQ_T$ at large Q_T , the mean value $\langle Q_T \rangle$ is about 3.6 times the value of Q_T at which the peak occurs in the distribution. We observe that $\langle Q_T \rangle$ grows from about 35 GeV at $m_h = M_Z$ to about 54 GeV at $m_h = 200$ GeV. The curve is nearly a straight line over the range shown, with $\langle Q_T \rangle \simeq 0.18m_h + 18$ GeV. In

computing the averages, we switch from the “total” result for $d\sigma/dy dQ_T$ shown, for example, in Fig. 6 to the fixed-order perturbative result when the fixed-order answer is the larger of the two choices above $Q_T = Q$. We extend our numerical integrations to the kinematic limit in the cases of $\langle Q_T \rangle$ and $\langle Q_T^2 \rangle$ in order to achieve insensitivity of the results to the upper limit of integration. The nearly linear growth of $\langle Q_T \rangle$ and of $\langle Q_T^2 \rangle^{1/2}$ with m_h is a reflection of the fact that the peak location in Q_T of the distribution $d\sigma/dy dQ_T$ grows in nearly linear fashion as m_h increases. Since $Q_T \sim 1/b$, the expression for the saddle point, Eq. (28), suggests that $\langle Q_T \rangle \propto 1/b_{\text{SP}} \propto m_h^\lambda$, with fractional power λ , rather than a nearly linear behavior. We remark that for large m_h , a linear fit is a good approximation to the fractional power dependence over a restricted range in m_h .

FIG. 10: Predictions of (a) the average value of the transverse momentum and (b) the root-mean-square for Higgs boson production as a function of Higgs boson mass at $\sqrt{S} = 14$ TeV and fixed rapidity $y = 0$. We show results for Higgs boson masses m_h from M_Z to 200 GeV.

For comparison with our results for Higgs boson production, we quote our predictions for Z production: $\langle Q_T \rangle = 25$ GeV and $\langle Q_T^2 \rangle^{1/2} = 38$ GeV. We note that the difference $\langle Q_T^h \rangle - \langle Q_T^Z \rangle \simeq 10$ GeV at $m_h = M_Z$, a manifestation of more significant gluonic radiation in Higgs boson production. The harder Q_T spectrum suggests that the signal to

background ratio can be enhanced if Higgs bosons are selected with large Q_T , a point to which we return in Sec. VI.

Choices of variable parameters are made in obtaining our results, and it is important to examine the sensitivity of the results to these choices. The parameter choices include the specification of the renormalization/factorization scale μ , the non-perturbative input, and $Q_T^{\min}$. Uncertainties of a different sort are associated with the order in perturbation theory at which we work.

FIG. 11: Renormalization/factorization scale μ dependence of the differential cross section $d\sigma/dy dQ_T$ as a function of Q_T for Higgs boson mass $m_h = 125$ GeV at $\sqrt{s} = 14$ TeV and fixed rapidity $y = 0$. We show results for three choices of the scale. In (a) the region of low and intermediate Q_T is shown in expanded form to illustrate the variation of the position in Q_T of the maximum of the distribution.

Dependence on the renormalization/factorization scale μ is often a good indicator of theoretical uncertainty. In Fig. 11, we show this dependence for the differential cross section $d\sigma/dQ_T$ at Higgs boson mass $m_h = 125$ GeV. Since we are interested principally in examining scale dependence of the resummed result, we fix the scale in the purely perturbative remainder term Eq. (53) to be $\mu = 0.5\sqrt{m_h^2 + Q_T^2}$. This term is not important in the re-

gion of modest Q_T where the cross section is large. We present results for three choices of the scale in the resummed term, Eqs. (3) and (26). All these results are obtained with $Q_T^{\min} = 0.3 \text{ GeV}$. We select as default choice $\mu = c/b$ with $c = 2e^{-\gamma_E}$ such that the scale varies with the integration variable b . The other two choices are independent of b but are proportional to the mass of the Higgs boson, $\mu = 0.5m_h$ and $\mu = 2m_h$. Scale dependence is not insignificant in the region where the distribution is large. It can shift the position of the peak by about 1 GeV, with corresponding changes in the normalization of the distribution above and below the position of the peak. The value of $d\sigma/dy dQ_T$ at the peak position is shifted by 4 to 5%. The shift in the location of the peak is about the same as the shift that occurs between resummation done at leading-logarithmic (LL) accuracy and at NLL accuracy [46].

FIG. 12: *Dependence of the differential cross section $d\sigma/dy dQ_T$ on the parameter $Q_T^{\min}$ as a function of Q_T for Higgs boson mass $m_h = 125 \text{ GeV}$ at $\sqrt{s} = 14 \text{ TeV}$ and fixed rapidity $y = 0$. We show results for three values of $Q_T^{\min}$, divided by the results for $Q_T^{\min} = 0$.*

For our central results we select $Q_T^{\min} = 0.3 \text{ GeV}$. We examine changes associated with

this parameter in Fig. 12. The ratio shown is

$$R_{\text{shift}} = \frac{d\sigma}{dydQ_T}(Q_T^{\min}) / \frac{d\sigma}{dydQ_T}(Q_T^{\min} = 0). \quad (57)$$

We vary $Q_T^{\min}$ over the range 0 to 500 MeV. The position of the peak of the Q_T distribution is very stable; within a bin width of 1 GeV, there is no change in the location of the peak. At $m_h = 125$ GeV the change in the value of $d\sigma/dydQ_T$ at the peak location of ~ 11.5 GeV is only 0.2% when $Q_T^{\min}$ varies from 0 to 0.3 GeV. However, for $Q_T < 1$ GeV, the uncertainties are much larger. One message from this exercise is that the resummed Q_T distribution cannot be computed reliably when $Q_T \ll Q_T^{\text{peak}}$, a conclusion that should not be surprising. On the other hand, the uncertainties in the Q_T distribution in the region of small Q_T associated with the choice of $Q_T^{\min}$ should not be worse than potential uncertainties in the data.

FIG. 13: *Dependence of the differential cross section $d\sigma/dydQ_T$ on the non-perturbative parameters (a) G_2 and (b) b_{max} as a function of Q_T for Higgs boson mass $m_h = 125$ GeV at $\sqrt{s} = 14$ TeV and fixed rapidity $y = 0$. We show results for two choices of each parameter.*

In Fig. 13 we examine the dependence of our predictions on the choice of the non-perturbative parameters b_{max} , g_2 , and $\bar{g}_2$. We combine the dependence on the latter two

parameters in a function $G2 = g_2 \ln(Q^2 b_{\max}^2 / c^2) + \bar{g}_2$, defined in Ref. [32]. In Fig. 13(a) we plot the ratio of the Q_T distribution with residual power corrections over its value without these contributions. In Ref. [32], $G2 = 0.4 \text{ GeV}^2$ is shown to produce the best fit to Tevatron data on W and Z boson production. To enhance the possible influence of power corrections, we choose parameters that are a few times larger than are needed in W and Z production. In Fig. 13(a), the values $G2 = 0.8 \text{ GeV}^2$ and 1.6 GeV^2 are used, twice- and four-times the values determined earlier. The corresponding changes in the predictions for Higgs boson production are very small. In Fig. 13(b), we examine sensitivities to the choice of $b_{\max}$. The ratio displayed is $R(b_{\max}) = d\sigma/dy dQ_T(b_{\max})/d\sigma/dy dQ_T(b_{\max} = 0.5 \text{ GeV}^{-1})$. For changes in $b_{\max}$ between 0.3 and 0.8 GeV^{-1} , the uncertainties in our predictions are much much less than 1%. They are consistent with the level of accuracy of our numerical computations. Evident in Fig. 13 is that the formulation we use to describe the non-perturbative region has no effect on the behavior of differential cross section at large Q_T .

Comparison of Figs. 11 and 13 shows that uncertainties related to scale variation are greater than uncertainties associated with non-perturbative physics. Uncertainties associated with physics in the region of large b are at most 1 to 2% depending on the size of the power corrections we introduce, whereas scale dependence can change distributions by more than 10%, if one examines the spectrum as a whole, and by about 5% in the region of the peak. Non-perturbative effects vanish very quickly as Q_T increases, while sensitivity to the scale choice increases as Q_T increases. Variations associated with non-perturbative physics in the large b region are much smaller at LHC energies than higher-order corrections to the perturbative functions A , B , and C .

A different resummation scheme, such as discussed in Ref. [43], can lead to uncertainties similar to those shown in Fig. 11 of this paper and in Fig. 7 of Ref. [46]. Because our method for extrapolation into the nonperturbative large b region is different, we expect the locations of the maxima in the distributions $d\sigma/dy dQ_T$ in Fig. 7 of Ref. [46] to shift to somewhat larger values of Q_T .

VI. CONCLUSIONS

Discovery of the Higgs particle is essential to shed light on the mechanism of electroweak symmetry breaking. The partonic subprocess $g+g \rightarrow hX$ dominates Higgs boson production

in hadronic reactions when the Higgs boson mass is in the expected range $m_h < 200$ GeV. The two-scale nature of the production dynamics, with mass m_h and transverse momentum Q_T both potentially large, and the fact that the fixed-order perturbative QCD contributions are singular as $Q_T \rightarrow 0$, necessitates all-orders resummation of large logarithmic contributions in order to obtain meaningful predictions for the Q_T distribution particularly in the region of modest Q_T where the cross section is largest. We perform this resummation of multiple soft-gluon emissions using an impact parameter b -space formalism. At LHC energies, the typical values of the incident parton momentum fractions $x_A \sim x_B \sim m_h/\sqrt{S} \sim 0.009$ (for $m_h = 125$ GeV) are small, and the gluon distribution evolves steeply at small x . Consequently, the saddle point in b of the Fourier transform from b -space to Q_T space is well into the region of perturbative validity. The resummed Q_T distributions are therefore determined primarily by the perturbatively calculated b -space distributions at small b , with negligible contributions from the non-perturbative region of large b . Our resummation formalism has excellent predictive power for the Q_T distributions of Higgs boson and Z production at the LHC energy, $\sqrt{S} = 14$ TeV, for Q_T as large as the respective boson masses Q . An examination of the numerical sensitivity of our results to variations in the renormalization/factorization scale μ and to parameters associated with the form of the assumed non-perturbative function at large b shows the expected modest dependence of μ and essentially no dependence on the non-perturbative parameters, except in the region of extremely small Q_T .

In this paper, we present predictions for the Q_T distributions of Higgs boson and Z production at $\sqrt{S} = 14$ TeV. Results are shown in Figs. 6 - 10. At the same mass, $m_h = M_Z$, the predicted mean value $\langle Q_T \rangle$ is about 10 GeV larger for Higgs boson production than for Z boson production. For the Higgs boson, $\langle Q_T \rangle$ grows from about 35 GeV at $m_h = M_Z$ to about 54 GeV at $m_h = 200$ GeV, and the root-mean-square $\langle Q_T^2 \rangle^{1/2}$ from about 59 GeV to about 87 GeV.

Searches for the Higgs boson in its decay to two photons require an excellent understanding of the production characteristics of both the signal and backgrounds. The primary background to direct photon production comes from decays of hadrons such as π^0 , η^0 , and ω^0 , themselves produced copiously at large transverse momentum from the fragmentation of jets, as well as from misidentified photons (*e.g.*, from processes that produce two jets or a jet and a photon and in which jets are misidentified as photons). Even after excellent

photon/jet discrimination and application of photon isolation restrictions, simulations show ratios of the expected signal to irreducible backgrounds in the range of 4 to 5×10^{-2} for m_h in the interval 120 to 130 GeV [7]. The irreducible backgrounds arise from the QCD annihilation $q\bar{q} \rightarrow \gamma\gamma$, the Compton $qg \rightarrow \gamma\gamma q$ (with one of the final photons produced from parton fragmentation (generalized bremsstrahlung)), and the gluon box $gg \rightarrow \gamma\gamma$ subprocesses, and their counterparts at higher orders of perturbation theory [13, 14, 15]. Although there is some dependence on the di-photon invariant mass and photon transverse momentum, the contributions of the annihilation and gluon box processes are comparable, and the fragmentation processes make a smaller contribution than either of these others. Of interest to us is the expected dependence of the ratio of signal to irreducible background. In this paper we provide predictions for the transverse momentum distribution of the signal. The gluon box subprocess has the same initial state as the inclusive gluon fusion process that produces the Higgs boson. Consequently, for di-photon invariant mass $M_{\gamma\gamma} = m_h$, we expect that the transverse momentum spectrum of the gluon box contribution to the irreducible background will have the same shape after soft gluon resummation as that for the Higgs boson. However, the other major component of the irreducible background, the annihilation $q\bar{q} \rightarrow \gamma\gamma$ subprocess, has the same initial state structure as Z boson production. As we show in this paper, the Q_T spectrum of Z production is predicted to be softer than that for Higgs boson production (*c.f.*, Figs. 9 and 10). We suggest therefore that a selection of events with large $Q_T^{\gamma\gamma}$ could help in significantly improving the signal to background ratio.
